(Received)

We study the magnetization plateau at $1/4$ of the saturation magnetization of the $S = 1$ antiferromagnetic spin ladder both analytically and numerically, with the aim of explaining recent experimental results on BIP-TENO by Goto *et al.* We propose two mechanisms for the plateau formation and clarify the plateau phase diagram on the plane of the coupling constants between spins.

KEYWORDS: spin ladder, magnetization plateau, frustration

The magnetization plateaux of low dimensional spin systems have been attracting much attention because of its full quantum nature. Very recently, a new organic tetraradical, 3,3',5,5'-tetrakis(*N*-tert-butylaminoxyl)biphenyl, abbreviated as BIP-TENO, has been synthesized.¹⁾ This material can be regarded as an $S = 1$ antiferromagnetic two-leg spin ladder, as explained later. Goto *et al.*²⁾ measured the magnetization curve of BIP-TENO at low temperatures in pulsed high magnetic fields up to about 50 T. They found $M \simeq 0$ up to about $H_{c1} \simeq 10$ T, suggesting the non-magnetic ground state, which was consistent with the result of susceptibility measurement. Another remarkable nature of their magnetization curve is the plateau at $M = M_s/4$ above $H_{c2} \simeq 45$ T, where M_s is the saturation magnetization. Unfortunately the end of the $M_s/4$ plateau is unknown because of the limitation of the strength of their magnetic field.

Considering the structure of BIP-TENO, Katoh *et al.*¹⁾ proposed its model of Fig.1. Since the ferromagnetic coupling J_F is thought to be much larger than other antiferromagnetic couplings J'_{AF} and J_{AF1} , two spins coupled by J_F effectively form an $S = 1$ spin. Thus the model of Fig.1(b) is reduced to an $S = 1$ antiferromagnetic two-leg ladder, as shown in Fig.1(c). The relation between the coupling constants of these two models are

$$J_{\perp} = J_{AF1}, \quad J_1 = (1/4)J'_{AF}. \quad (1)$$

In the following, we consider the model of Fig.1(c) to investigate the $M_s/4$ magnetization plateau of this model at zero temperature. The plateau at $M = 0$ is interpreted as the manifestation of the Haldane state. On the other hand, the $M_s/4$ plateau is not easily understood. The necessary condition for the quantized magnetization plateau by Oshikawa, Yamanaka and Affleck³⁾ is

$$Q(S_{\text{unit}} - \langle m \rangle) = \text{integer}, \quad (2)$$

where Q is the spatial period of the wave function of the state measured by the unit cell, S_{unit} and $\langle m \rangle$ are the total spin and the magnetization per unit cell, respec-

Fig. 1. (a) Schematic illustration of BIP-TENO. Open circles represent $S = 1/2$ spins. (b) Plane type illustration of BIP-TENO. (c) Effective model of BIP-TENO in case of $J_F \rightarrow \infty$. Open ellipses represent $S = 1$ spins.

tively. Applying the theorem to our model, $S_{\text{unit}} = 2$ and $m = 1/2$, this condition is not satisfied if $Q = 1$. Thus, $Q = 2$ is required at least, which means the occurrence of the spontaneous symmetry breaking in the $M_s/4$ plateau state. The magnetization plateaux caused by the spontaneous symmetry breaking were discussed for the $M_s/2$ plateau of the $S = 1/2$ zig-zag ladder^{4,5,6)} (equivalent to the bond-alternating chain with next-nearest-neighbor interactions), the $M_s/2$ plateau of the $S = 1/2$ ladder,^{7,8,9,10)} and also the $(2/3)M_s$ plateau of the $S = 1/2$ distorted diamond chain,^{11,12)} and so on.

The Hamiltonian of the model of Fig.1(c) is

$$\hat{H} = J_1 \sum_{l=1,2} \sum_{j=1}^L \mathbf{S}_{l,j} \cdot \mathbf{S}_{l,j+1} + J_{\perp} \sum_{j=1}^L \mathbf{S}_{1,j} \cdot \mathbf{S}_{2,j}$$

$$+H \sum_{l=1,2} \sum_{j=1}^L S_{l,j}^z \quad (3)$$

where $\mathbf{S}$ denotes the spin-1 operator, j the rung number and $l = 1, 2$ the leg number. The last term is the Zeeman energy in the magnetic field H . When $J_{\perp} = 0$, our model is reduced to that of two independent usual $S = 1$ chains, in which no plateau is expected in the magnetization curve except at $M = 0$.

Let us consider the opposite limit $J_{\perp} \gg J_1$ by use of the degenerate perturbation theory. When $J_1 = 0$, all the rung spin pairs are mutually independent. In this case, at $M_s/4$, half of the rung spin pairs are in the state

$$\psi(0,0) = (1/\sqrt{3})(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle - |00\rangle) \quad (4)$$

and the remaining half pairs are in the state

$$\psi(1,1) = (1/\sqrt{2})(|\uparrow\uparrow\rangle + |\downarrow\downarrow\rangle) \quad (5)$$

where $\psi(S_{\text{tot}}, S_{\text{tot}}^z)$ is the wave function of two $S = 1$ spins coupled by antiferromagnetic interaction $J_{\perp}$ with the quantum numbers S_{tot} and S_{tot}^z . These wave functions have lowest energies in the subspace of $S_{\text{tot}}^z = 0$ and $S_{\text{tot}}^z = 1$, respectively. Other possible selections have higher energies. The $M_s/4$ state is highly degenerate as far as $J_1 = 0$, because there is no restriction for the configurations of these two states. This degeneracy is lifted up by the introduction of J_1 . To investigate the effect of J_1 , we introduce the pseudo-spin $\mathbf{T}$ with $T = 1/2$. The $|\uparrow\rangle$ and $|\downarrow\rangle$ states of the $\mathbf{T}$ spin correspond to $\psi(1,1)$ and $\psi(0,0)$, respectively. Neglecting other seven states for the rung spin pairs, the effective Hamiltonian can be written as

$$\hat{H}_{\text{eff}} = \sum_j \{ J_{\text{eff}}^{xy} (T_j^x T_{j+1}^x + T_j^y T_{j+1}^y) + J_{\text{eff}}^z T_j^z T_{j+1}^z \} \quad (6)$$

in the lowest order of J_1 , where

$$J_{\text{eff}}^{xy} = (8/3)J_1, \quad J_{\text{eff}}^z = (1/2)J_1 \quad (7)$$

Thus the $M_s/4$ plateau problem of the original model is mapped onto the $M = 0$ problem of the usual $T = 1/2$ antiferromagnetic XXZ spin chain with the nearest-neighbor (NN) interaction. As is well known, depending on whether $\Delta_{\text{eff}} \equiv J_{\text{eff}}^z/J_{\text{eff}}^{xy} \leq 1$ or $\Delta_{\text{eff}} > 1$, the ground state of eq.(6) is either the spin-fluid state (gapless) or the Néel state (gapful), which correspond to the no-plateau state or the plateau state of the original model, respectively.

We see $\Delta_{\text{eff}} = 3/16$ from eq.(7), which means no $M_s/4$ plateau in the model of Fig.1(c), at least when $J_{\perp} \gg J_1$. As already stated, there is no $M_s/4$ plateau also when $J_{\perp} = 0$. Thus the $M_s/4$ plateau will not appear in the whole region of $J_1/J_{\perp}$ for the model of Fig.1(c), although we cannot completely exclude the possibility of the $M_s/4$ plateau at the intermediate region. We note that the absence of the $M_s/4$ plateau is also established by numerical method, as shown later in Fig.4.

In previous works for the $M_s/2$ plateau of the $S = 1/2$ spin ladder,^{7,8,9,10} it has shown that the second and/or third neighbor interactions bring about the plateau.

Fig. 2. $S = 1$ ladder model with second and third neighbor interactions.

Considering this fact, let us introduce the second (J_2) and third (J_3) neighbor interactions to our model, as shown in Fig.2. Including these interactions, the effective Hamiltonian (6) is modified to the generalized version of the $T = 1/2$ XXZ Hamiltonian with the NN and the next-nearest-neighbor (NNN) interactions:

$$\begin{aligned} \hat{H}_{\text{eff}} = & \sum_j \{ J_{\text{eff}}^{xy} (T_j^x T_{j+1}^x + T_j^y T_{j+1}^y) + J_{\text{eff}}^z T_j^z T_{j+1}^z \} \\ & + \sum_j \{ J_{\text{eff}}^{xy(2)} (T_j^x T_{j+2}^x + T_j^y T_{j+2}^y) + J_{\text{eff}}^{z(2)} T_j^z T_{j+2}^z \} \end{aligned} \quad (8)$$

where

$$J_{\text{eff}}^{xy} = (8/3)(J_1 - J_2), \quad J_{\text{eff}}^z = (1/2)(J_1 + J_2) \quad (9)$$

$$J_{\text{eff}}^{xy(2)} = (8/3)J_3, \quad J_{\text{eff}}^{z(2)} = (1/2)J_4 \quad (10)$$

Note that the XXZ anisotropy parameters of the NN and NNN interactions are different with each other in general. In this model, three phases are expected:^{13,14} these are the spin-fluid state (gapless), the Néel state (gapful) and the dimer state (gapful).

For simplicity, first we consider the $J_2 > 0$, $J_3 = 0$ case. In this case, the NNN interaction in eq.(8) vanishes and the anisotropy parameter is

$$\Delta_{\text{eff}} = \frac{3}{16} \frac{J_1 + J_2}{J_1 - J_2} \quad (11)$$

Therefore the Néel condition $\Delta_{\text{eff}} > 1$ is satisfied when $J_2/J_1 > 13/19$. This type of $M_s/4$ plateau is due to the Néel mechanism and called plateau A from now on.

Next we consider the $J_2 = 0$, $J_3 > 0$ case. In this case, the anisotropy parameters of the NN and NNN interactions have the same value $\Delta_{\text{eff}} = 3/16$ and $J_{\text{eff}}^{xy(2)}/J_{\text{eff}}^{xy} = J_{\text{eff}}^{z(2)}/J_{\text{eff}}^z = J_3/J_1$. From the phase diagram of $S = 1/2$ XXZ chain with the NN and NNN interactions,^{13,14} the ground state of (8) at $\Delta_{\text{eff}} = 3/16$ is either the spin-fluid state or the dimer state depending on whether $J_3/J_1 < 0.31$ or $J_3/J_1 > 0.31$. This type of $M_s/4$ plateau, which is brought about by the dimer mechanism, is called plateau B.

The physical pictures of these two plateau states are shown in Fig.3. As is clear from Fig.3, both plateau states are doubly degenerate due to the spontaneous symmetry breaking. Then the period of the state is $Q = 2$ in both plateau states, from which we see the

Fig. 3. (a) Physical picture of the plateau A (Néel mechanism). Open and shaded ellipses represent $\psi(0,0)$ and $\psi(1,1)$ states of the rung pairs ($|\downarrow\rangle$ and $|\uparrow\rangle$) in the T picture, respectively. (b) Physical picture of the plateau B (dimer mechanism).

realization of the necessary condition eq.(2). The transition from the no-plateau state to the plateau A or B state (in the language of T , from the spin-fluid state to the Néel or dimer state) is of the Berezinskii-Kosterlitz-Thouless^{15,16} (BKT) type.^{13,14} In general case $J_2, J_3 > 0$, the transition from the plateau A state to the plateau B state may occur, which has the Gaussian universality.^{13,14}

We have performed numerical diagonalization by Lanczos method up to 16 spins for the $S = 1$ model with J_2 and/or J_3 to confirm to existence of two plateaux, predicted by use of the degenerate perturbation theory. As already stated, the transition from the no-plateau state to the plateau A or B state is of the BKT type, of which boundary is very difficult to determine from the numerical data when the conventional methods are used. This is mainly due to the logarithmic size corrections associated with the BKT transition. We have used the level spectroscopy method,^{6,9,10,17,14,18} by use of which the BKT phase boundary can be determined free from the most dominant logarithmic size corrections. In the level spectroscopy method, we use three excitations defined by (for simplicity we are writing the $L = 4n$ case, n being an integer)

$$\Delta_1 \equiv \frac{1}{2} \left\{ E_0 \left(L, \frac{L}{2} + 1, \pi \right) + E_0 \left(L, \frac{L}{2} - 1, \pi \right) - E_0 \left(L, \frac{L}{2}, 0 \right) \right\} \quad (12)$$

$$\Delta_{0A} \equiv E_A \left(L, \frac{L}{2}, \pi \right) - E_0 \left(L, \frac{L}{2}, 0 \right) \quad (13)$$

$$\Delta_{0B} \equiv E_B \left(L, \frac{L}{2}, \pi \right) - E_0 \left(L, \frac{L}{2}, 0 \right) \quad (14)$$

where $E_0(L, M, k)$ means the lowest eigenvalue of the $S = 1$ ladder Hamiltonian in the subspace where the eigenvalue of the operator $S_{\text{tot}}^z \equiv \sum_l \sum_j S_{l,j}^z$ is M with the momentum k and system size $L = 4n$ under the periodic boundary condition. $E_0(L, L/2, 0)$ is nothing but the ground state energy. E_{0A} is the lowest energy with

$M = L/2$, $k = \pi$ subspace having the eigenvalue $P = -1$ for the space inversion operation of the rung number $i \rightarrow L - i + 1$. This excitation is called Néel excitation. We have $P = -1$ for E_{0B} , which is named dimer excitation. In the no-plateau state, plateau A state and plateau B state, the lowest excitations should be Δ_1 , Δ_{0A} and Δ_{0B} , respectively. Thus the boundaries between these three phases can be determined from the crossing points among these three excitations with sweeping the coupling constants.¹⁴

Fig. 4. The $M_s/4$ plateau phase diagram (a) on the $\tilde{J}_1 - \tilde{J}_2$ plane when $J_3 = 0$, and (b) on the $\tilde{J}_1 - \tilde{J}_3$ plane when $J_2 = 0$. Here $\tilde{J}_i \equiv J_i/J_\perp$ for $i = 1, 2, 3$. The closed diamonds represent the BKT phase boundaries and open circles the first order phase boundaries.

By use of the level spectroscopy, we obtain the $M_s/4$ plateau phase diagrams in Fig.4. The estimated error bars of the boundary points are much smaller than the size of marks. The line symmetry with respect to the line $\tilde{J}_2 = \tilde{J}_1$ in Fig.4(a) is due to the equivalence of the model for interchanging $J_1 \leftrightarrow J_2$ when $J_3 = 0$. The slope of the BKT lines near the origin are very close to the predicted values, 13/19 in Fig.4(a) and 0.31 in Fig.4(b),

Fig. 5. (a) Classical picture of (a) the no-plateau 1 state, and (b) no plateau 2 state.

which confirms the high reliability of our analysis of the numerical data by use of the level spectroscopy method. In Fig.4(a), there are two no-plateau phases,^{8,9,19)} of which classical pictures are shown in Fig.5. Note that the long range order is destroyed by quantum fluctuations in no-plateau states. The boundaries between two no-plateau states are determined by the crossing of the ground state.

Following the present study, the critical value of J_3 for the realization of the plateau when $J_2 = 0$ is smaller than that of J_2 when $J_3 = 0$, irrespective of the value of J_1 . Furthermore the plateau B phase can appear for any value of $\tilde{J}_1$, although the plateau A cannot be realized for larger values of $\tilde{J}_1$. Thus the plateau B is easier to be realized than the plateau A.

One may think that there should exist dashed-line interactions in Fig.6(a). The model of Fig.6(a) has four bond-alternating $S = 1/2$ chains. At a glance, the unit cell seems to consist of eight $S = 1/2$ spins, which may brings about the $M_s/4$ plateau without any spontaneous symmetry breaking. However, the model of Fig.6(a) can be re-drawn in the plane form of Fig.6(b), indicating that the unit cell is still composed of four $S = 1/2$ spins. Thus this new interaction cannot be the direct reason for the $M_s/4$ plateau. In fact, in the degenerate perturbation theory used in this letter, this new interaction only modifies J_{eff}^{xy} and J_{eff}^z in eq.(7) without changing their ratio $\Delta_{\text{eff}} = J_{\text{eff}}^{xy}/J_{\text{eff}}^z$. A similar situation can be found in two-leg bond-alternating ladder investigated by Cabra and Grynberg.²⁰⁾

In conclusion, we have investigated the $M_s/4$ plateau of the $S = 1$ spin ladder, proposing two mechanisms for the plateau. We have also clarified the plateau-no plateau phase diagram by use of the degenerate perturbation theory, and the level spectroscopy analysis of the numerical diagonalization data. The full study of the magnetization process of the present model will be published elsewhere.

Acknowledgments

We would like to express our appreciations to Dr. Yuko Hosokoshi (Institute for Molecular Science) and Prof. Tsuneaki Goto (ISSP, University of Tokyo) for
